

CHAPTER 15, SECTION 6

SPEECHrecognition (briefly)

- ◊ Word sequences
- ◊ Word pronunciation
- ◊ Speech sounds
- ◊ Speech as probabilistic inference

Outline

Words are the hidden state sequence, *signal* is the observation sequence

i.e., decomposes into acoustic model + language model

$$P(\text{Words}|\text{signal}) = \alpha P(\text{signal}|\text{Words})P(\text{Words})$$

Use Bayes' rule:

i.e., choose *Words* to maximize $P(\text{Words}|\text{signal})$

What is the **most likely** word sequence, given the speech signal?

Speech signals are noisy, variable, ambiguous

It's not easy to wreck a nice beach

Speech as probabilistic inference

Example, “celling” is [s iy | ih ngl] / [s iy | ix ngl] / [s iy | enl]

ARPAbet designed for American English

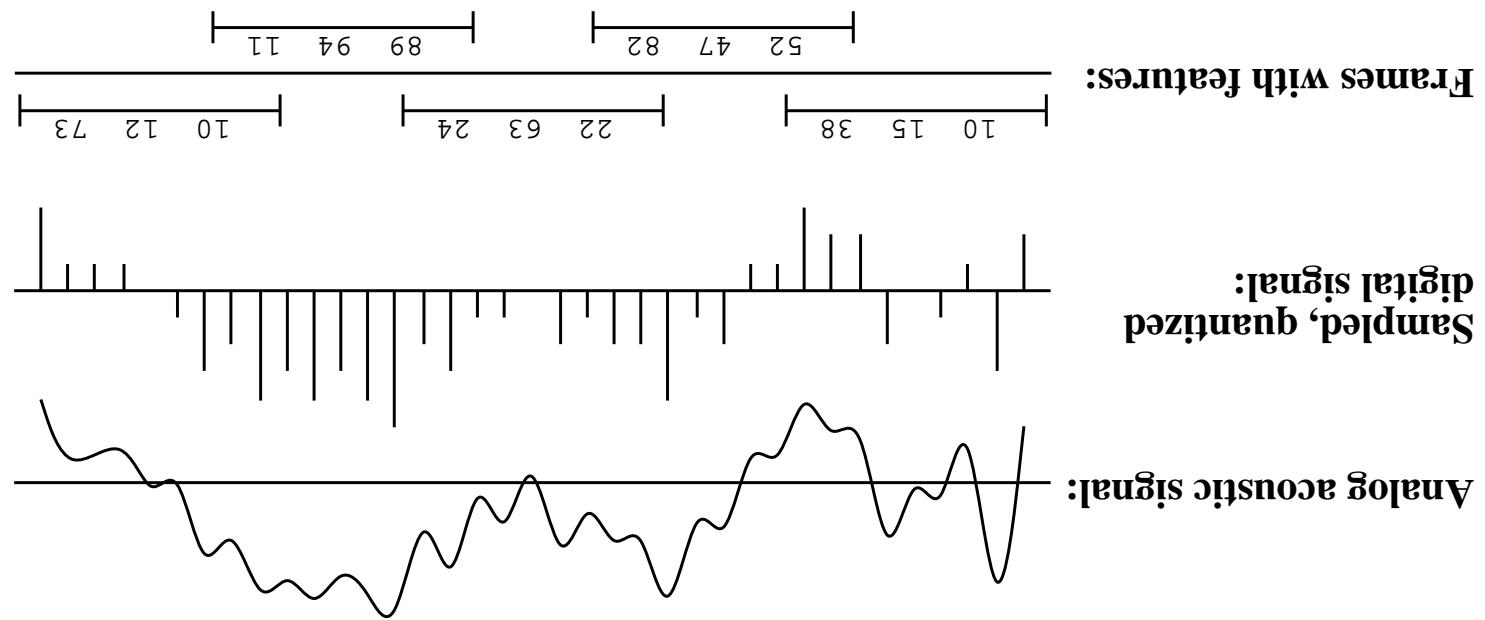

acoustic model = pronunciation model + phone model

Form an intermediate level of hidden states between words and signal

All human speech is composed from 40-50 phones, determined by the configuration of articulators (lips, teeth, tongue, vocal cords, air flow)

Phones

Frame features are typically **formants**—peaks in the power spectrum

Raw signal is the microphone displacement as a function of time;
processed into overlapping 30ms frames, each described by **features**

Speech sounds

Frame features in $P(\text{features}|\text{phone})$ summarized by

- an integer in $[0 \dots 255]$ (using vector quantization); or
- the parameters of a mixture of Gaussians

Three-state phones: each phone has three phases (Onset, Mid, End)

E.g., [t] has silent Onset, explosive Mid, hissing End

Triphone context: each phone becomes n^2 distinct phones, depending on the phones to its left and right

E.g., [t] in "star" is written $[t(s,aa)]$ (different from "tar"!)

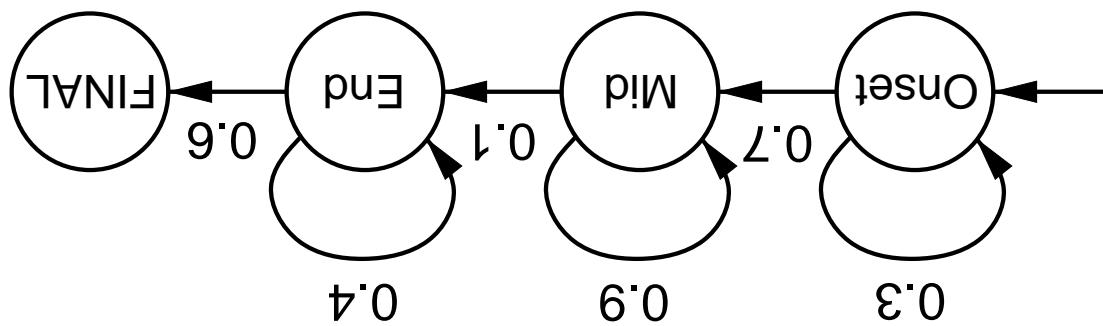

Triphones useful for handling coarticulation effects: the articulators have inertia and cannot switch instantaneously between positions

E.g., [t] in "eight" has tongue against front teeth

Phone models

Onset:	Mid:	End:	C1: 0.5	C3: 0.2	C4: 0.1	C2: 0.2	C4: 0.7	C6: 0.5	C3: 0.3	C5: 0.1	C7: 0.4
--------	------	------	---------	---------	---------	---------	---------	---------	---------	---------	---------

Output probabilities for the phone HMM:

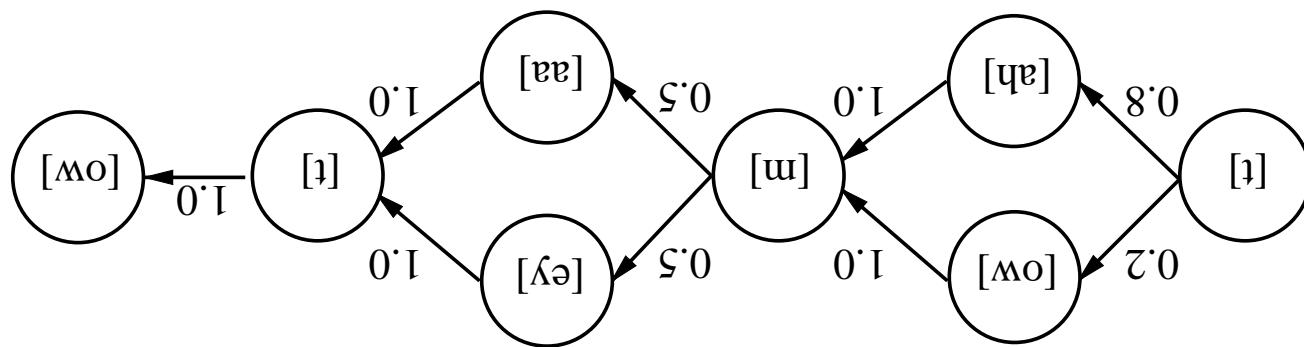

Phone HMM for [m]:

Phone model example

Structure is created manually, transition probabilities learned from data

$$P(\text{tahmeytow} \mid \text{"tomato"}) = P(\text{tahmataow} \mid \text{"tomato"}) = 0.4$$

$$P(\text{toumeytow} \mid \text{"tomato"}) = P(\text{toumataow} \mid \text{"tomato"}) = 0.1$$

Distribution represented as an HMM transition model

Each word is described as a distribution over phone sequences

Word pronunciation models

Isolated-word dictation systems with training reach 95–99% accuracy

$$\text{and then } P(e_{1:t}|word) = \sum_{\mathbf{x}} p_{e_{1:t}}(\mathbf{x})$$

$$p_{e_{1:t+1}} = \text{FORWARD}(e_{1:t}, e_{t+1})$$

and use the recursive update

$$p_{e_{1:t}} = \mathbf{P}(\mathbf{X}_t, e_{1:t})$$

$P(e_{1:t}|word)$ can be computed recursively: define

Prior probability $P(word)$ obtained simply by counting word frequencies

$$P(word|e_{1:t}) = \alpha P(e_{1:t}|word) P(word)$$

Phone models + word models fix likelihood $P(e_{1:t}|word)$ for isolated word

Isolated words

Continuous speech systems manage 60–80% accuracy on a good day

- Adjacent words highly correlated
- Sequence of most likely words \neq most likely sequence of words
- Segmentation: there are few gaps in speech
- Cross-word coarticulation—e.g., “next thing”

Not just a sequence of isolated-word recognition problems!

Continuous speech

More sophisticated models (trigrams, grammars, etc.) help a little bit

Train by counting all word pairs in a large text corpus

$$P(w_i | w_1 \dots w_{i-1}) \approx P(w_i | w_{i-1})$$

Bigram model:

$$P(w_1 \dots w_n) = \prod_u P(w_i | w_1 \dots w_{i-1})$$

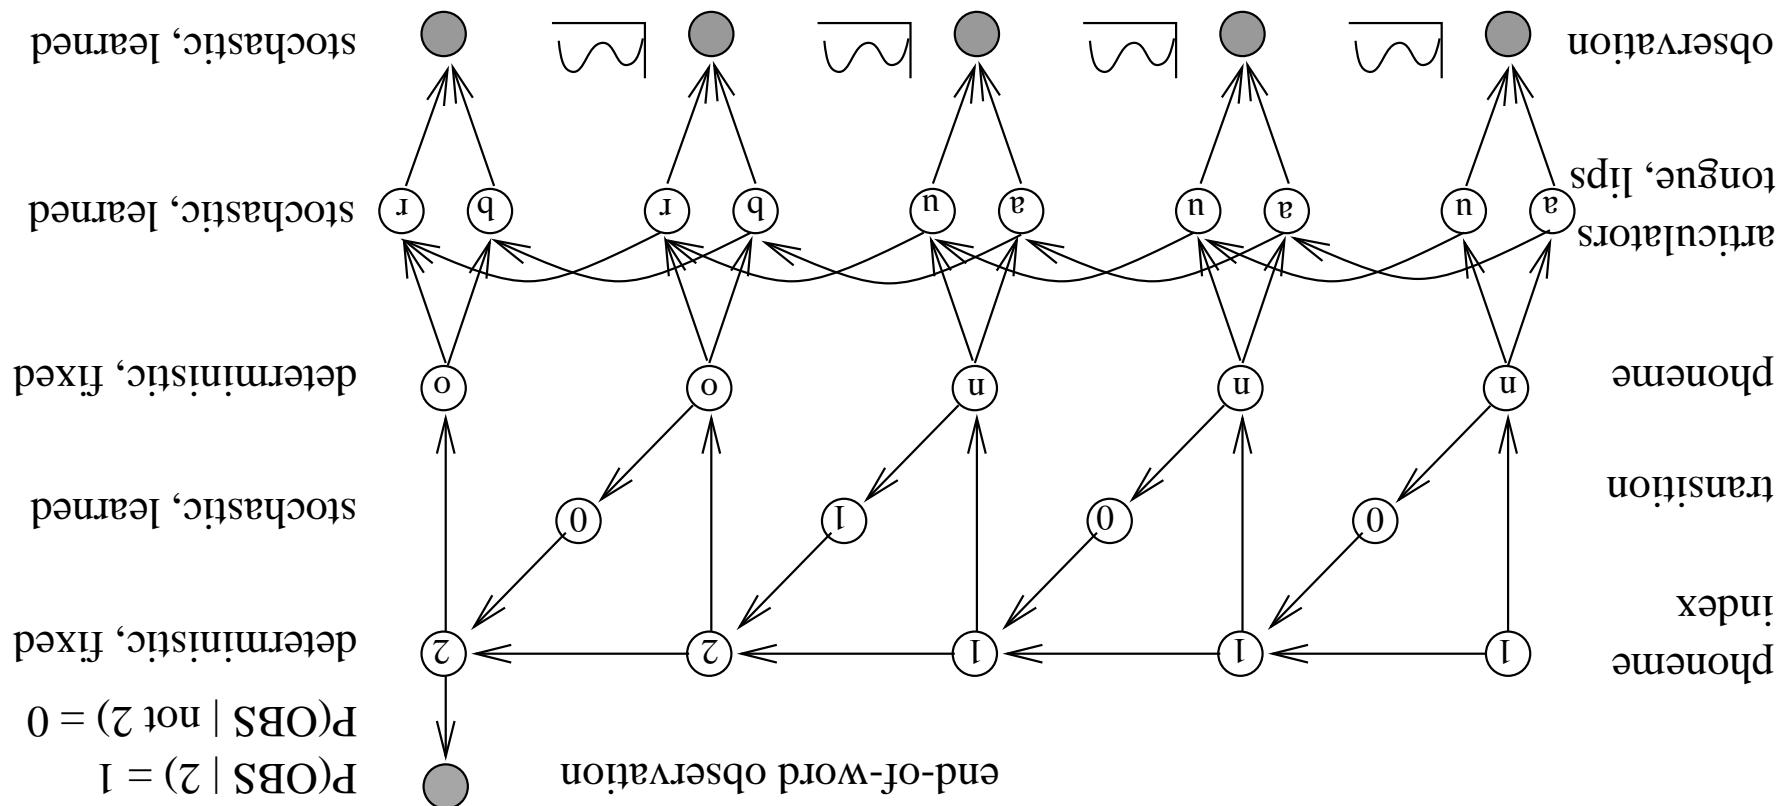

Prior probability of a word sequence is given by chain rule:

Language model

Viterbi algorithm finds the most likely **Phone state** sequence
the word we're in + the phone in that word + the phone state in that phone
States of the combined language+word+phone model are labelled by
Does segmentation by considering all possible word sequences and boundaries
Doesn't always give the most likely word sequence because
each word sequence is the sum over many state sequences
Jelinek invented A* in 1969 a way to find most likely word sequence
where "step cost" is $-\log P(u_i | u_{i-1})$

Combined HMM

Also easy to add variables for, e.g., gender, accent, speed. Zweig and Russell (1998) show up to 40% error reduction over HMs

DBNs for speech recognition

Since the mid-1970s, speech recognition has been formulated as probabilistic inference = speech signal, hidden variables = word and phone sequences "Context" effects (coarticulation etc.) are handled by augmenting state Variability in human speech (speed, timbre, etc., etc.) and background noise make continuous speech recognition in real settings an open problem

Summary
